***In Situ* Modification and Manipulation of
Stem Cells of the Central Nervous System**

Field of the Invention

The present invention is directed to the *in situ* (*in vivo*) modification and
5 manipulation, via genetic or epigenetic means, of endogenous precursor cells in the
mammalian central nervous system (CNS) and compositions for inducing *in situ*
modification and manipulation of CNS precursor cells. More particularly, the
invention is related to a method of directly manipulating the endogenous precursor
cells *in situ* (*in vivo*) for the purpose of using them as vehicles for the delivery of
10 agents to the CNS or to induce them to divide, differentiate and migrate so as to
replace dysfunctional cells or those lost to injury or disease.

Background of the Invention

Development of the mammalian nervous system begins in the early stage of fetal
development and continues until the early post-natal period. The mammalian
15 central nervous system (CNS) is composed of three cell types: neurons, astrocytes
and oligodendrocytes. While neurons are generated primarily during the fetal
period, oligodendrocytes and astrocytes are generated during the early post-natal
period. By the late post-natal period the CNS has its full complement of nerve
cells.

20 Unlike many other cells found in different tissues, the differentiated cells of the
adult mammalian CNS have little or no ability to enter the mitotic cycle and
generate new nerve cells. While it is believed that there is a limited and slow
turnover of astrocytes [Korr et al., *J. Comp. Neurol* 150:169, (1971)] and that

progenitors for oligodendrocytes [Wolsqijk and Noble, *Development* 105:386, (1989)] are present, the generation of new neurons does not occur. While a few mammalian species (e.g. rats) exhibit the limited ability to generate new neurons in restricted adult brain regions such as the dentate gyrus and olfactory bulb [Kaplan, 5 *J. Comp. Neurol.* 195:323, (1981); Bayer, *N.Y. Acad. Sci.* 457:163, (1985)] this does not apply to all mammals; and the generation of new CNS cells in adult primates does not occur [Rakic, *Science* 227:1054, (1985)]. This inability to produce new nerve cells in most mammals (and especially primates) may be advantageous for long-term memory retention; however, it is a distinct disadvantage when the need to 10 replace lost neuronal cells arises due to injury or disease.

CNS disorders encompass numerous afflictions such as neurodegenerative diseases (e.g. Alzheimer's and Parkinson's), acute brain injury (e.g. stroke, head injury, cerebral palsy) and a large number of CNS dysfunctions (e.g. depression, epilepsy, and schizophrenia). In recent years neurodegenerative disease has become an 15 important concern due to the expanding elderly population which is at greatest risk for these disorders. These diseases, which include Alzheimer's Disease, Multiple Sclerosis, Huntington's Disease, Amyotrophic Lateral Sclerosis, and Parkinson's Disease, have been linked to the degeneration of neural cells in particular locations of the CNS, leading to the inability of these cells or the brain region to carry out 20 their intended function. In addition to neurodegenerative diseases, acute brain injuries often result in the loss of neural cells, the inappropriate functioning of the affected brain region, and subsequent behavior abnormalities. Probably the largest area of CNS dysfunction (with respect to the number of affected people) is not characterized by a loss of neural cells but rather by an abnormal functioning of 25 existing neural cells. This may be due to inappropriate firing of neurons, or the abnormal synthesis, release, and processing of neurotransmitters. Some of these dysfunctions are well studied and characterized disorders such as depression and epilepsy, others are less understood disorders such as neurosis and psychosis.

To date, treatment for CNS disorders has been primarily via the administration of 30 pharmaceutical compounds. Unfortunately, this type of treatment has been fraught with many complications including the limited ability to transport drugs across the

blood-brain barrier and the drug-tolerance which is acquired by patients to whom these drugs are administered long-term. For instance, partial restoration of dopaminergic activity in Parkinson's patients has been achieved with levodopa, which is a dopamine precursor able to cross the blood-brain barrier. However, 5 patients become tolerant to the effects of levodopa, and therefore, steadily increasing dosages are needed to maintain its effects. In addition, there are a number of side effects associated with levodopa such as increased and uncontrollable movement.

10 Recently, the concept of neurological tissue grafting has been applied to the treatment of neurodegenerative diseases such as Parkinson's Disease.

An emerging technology for treating neurological disorders entails the transplantation of cells into the CNS to replace or compensate for loss or abnormal functioning of the host's nerve cells. While embryonic CNS cells have given the best results in human trials [Winder *et al.*, *New Eng. J. Med.* 327:1556, (1992)] and 15 are the preferred donor tissue, due to ethical and political considerations which limit the use of these cells, other types of donor tissue are being developed. These include: genetically modified neural cell lines [Renfranz *et al.*, *Cell* 66:173, (1991); Synder *et al.*, *Cell* 68:1, (1992)], fibroblasts [Kawaja *et al.*, *J. Neurosci.*, 12:2849, (1992)], muscle cells [Jiao *et al.*, *Nature* 363:456, (1993)], glial progenitor cells 20 [Groves *et al.*, *Nature* 362:453, (1993)] and encapsulated cells [Hoffman *et al.*, *Exp. Neurol.* 132:100, (1993)].

While transplantation approaches represent a significant improvement over currently available treatments for neurological disorders, they suffer from a number of significant drawbacks. For example, upon transplantation, some cell types fail to 25 integrate with host tissue. Another disadvantage is that immunological incompatibility between donor and host could result in the rejection of the implanted cells. There is also the potential that the transplanted cells can result in tumor formation or pass infectious agents from the donor tissue to the host. Another significant drawback of transplantation procedures is that due to the

invasiveness of the procedures, which carry the risks involved in any major neurosurgical operation, damage to healthy brain tissue could occur.

Leblond [*NCI Monograph*, 14:19, (1963)] has classified adult mammalian tissue into three categories based on the rate of cell turnover within the population. These
5 are:

1. Static populations, like the nervous system, where there is little or no division and cells formed during development persist for the animal's lifetime;
- 10 2. Tissues having a conditionally renewing population of cells, such as the liver, where there is little cell division under normal conditions but where new cells can generate in response to an appropriate stimulus;
- 15 3. Continually renewing populations, such as the blood and squamous epithelium, where differentiated cells have a short life span and are continually being replaced by a subpopulation of cells referred to as stem cells.

The critical identifying feature of a stem cell is its ability to exhibit self-renewal or to generate more of itself. The simplest definition of a stem cell would be a cell with the capacity for self-maintenance. A more stringent (but still simplistic) definition of a stem cell is provided by Potten and Loeffler [*Development* 110:1001,
20 (1990)] who have defined stem cells as "undifferentiated cells capable of a) proliferation, b) self-maintenance, c) the production of a large number of differentiated functional progeny, d) regenerating the tissue after injury, and e) a flexibility in the use of these options."

The role of stem cells is to replace cells that are lost by natural cell death, injury or
25 disease. The presence of stem cells in a particular type of tissue usually correlates with tissues that have a high turnover of cells. However, this correlation may not

always hold as stem cells are thought to be present in tissues that do not have a high turnover of cells [e.g., liver; Travis, *Science*, 259:1829, (1993)].

The low turnover of cells in the mammalian CNS together with the inability of the adult mammalian CNS to generate new cells in response to the loss of cells

- 5 following injury or disease has lead to the assumption that the adult mammalian CNS does not contain stem cells. However, cells exhibiting stem cell characteristics *in vitro* have recently been isolated from the CNS. This cell is present in the embryo [Reynolds *et al.*, *J. Neurosci.* 12:4565, (1992)] through to the adult [Reynolds and Weiss, *Science* 255:1707, (1992)], suggesting that adult CNS, 10 although it does not generate new cells in response to injury or disease, has the capacity to generate new cells and to repair itself via proliferation and differentiation of stem cells and their progeny in a manner analogous to the hematopoietic system.

- In consideration of the limitation and deficiencies attendant in the prior art with 15 respect to therapies for treating CNS disorders, it is apparent that there exists a need in the art for a method of treating CNS disorders which involves replacing cells lost to injury or disease, but that does not involve invasive transplantation procedures and the disadvantages attendant with such procedures. In addition, due to the problems associated with pharmaceutical compounds, there exists a need in 20 the art for a method of treating CNS disorders which involves the direct delivery of compounds to the CNS by other CNS cells thereby circumventing the use of infusion pumps and the blood-brain barrier.

Summary of the Invention

- It is an object of this invention to provide a method for the replacement of cells lost 25 to injury, disease or dysfunction by inducing endogenous precursor cells to proliferate/differentiate and/or migrate within the CNS.

It is also an object of this invention to provide a method for the delivery of agents to the CNS by the genetic or epigenetic manipulation of endogenous precursor cells.

A further object of the invention is to provide compositions that are used to induce proliferation, differentiation and/or migration of endogenous CNS precursor cells and/or to genetically modify CNS precursor cells *in situ*.

Another object of this invention is to provide a method for increasing the *in vitro*
5 yield of stem cells by epigenetic manipulation of endogenous precursor cells.

These objects are accomplished by the methods disclosed below. Additional objects and features of the invention will be apparent to those skilled in the art from the following detailed description and appended claims when taken in conjunction with the figures.

10 A method for the *in situ* proliferation of neural precursor cells is described wherein one or more growth factors is administered to a ventricle of the central nervous system to induce the proliferation of the precursor cells.

A method for the *in situ* genetic modification of neural precursor cells is also described wherein genetic material is administered to a CNS ventricle to infect the
15 precursor cells. The genetic material encodes a neurological agent selected from the group consisting of growth factors, growth factor receptors, neurotransmitters, neurotransmitter receptors, neuropeptides, growth factor synthesizing enzymes, and neurotransmitter synthesizing enzymes.

Also disclosed is a method of *in vitro* proliferation of precursor cells comprising the
20 steps of administering one or more growth factors to a CNS ventricle of a living mammal, removing tissue lining the CNS ventricle, dissociating the tissue to separate precursor cells, and exposing the precursor cells to a culture medium containing a growth factor that induces proliferation of the cells.

A method of treating a mammal suffering from a neurological disorder caused by
25 lost or damaged neural cells is also described wherein one or more growth factors is administered to a CNS ventricle of the mammal to induce the *in situ*

proliferation, migration, and differentiation of precursor cells lining the ventricle so as to replace the lost or damaged neural cells.

Brief Description of the Figures

Figures 1a-1c show differentiated cells that were generated from stem cells isolated from the adult conus medullaris. Tissue containing the conus medullaris was dissected from adult mice. The stem cells were isolated and cultured in the presence of 20 ng/ml of EGF and bFGF together. They generated neurons, astrocytes, and oligodendrocytes as indicated by triple label indirect immunocytochemistry with antisera to MAP-2 (Fig. 1A), GFAP (Fig. 1B) and O4 (Fig. 1C) respectively.

Figure 2 shows the number of cells proliferating in the subependyma after various thymidine kill treatments. Control mice received no tritiated-thymidine (3H-thymidine) and were considered to have 100% of a proliferating subependymal cell population. Animals that received a series of injections on day 0 in order to kill the constitutively proliferating population of cells had 85% of control values on day 8. Animals that received a series of 3H-thymidine injections on day 0 and on day 2 had 45% of control values 8 days after the last injection (day 10). Animals that received a series of 3H-thymidine injections on day 0 and day 4 had 85% of control values on day 12. This suggests that stem cells are recruited into the proliferative mode two days after the initial kill and that most have become quiescent again by day 4.

Figure 3 shows the number of neurosphere formed *in vitro* from animals subjected to various 3H-thymidine treatments *in vivo*. Animals received the same series of injections as illustrated in Figure 2. Control animals received saline injections. Mice were sacrificed 16-20 hours following the last 3H-thymidine injection and the brains were removed and cultured in order to assess the number of neurospheres that formed following each thymidine kill treatment. Animals that received 3H-thymidine on day 0 (which kills the normally proliferating subependymal cells) formed the same number of spheres as control animals, suggesting that the constitutively proliferating subependymal cells are not the source of stem cells

isolated *in vitro*. Animals that received a second series of injections on day 2 formed 45% the number of neurospheres relative to control values. Animals that received a second series of injections on day 4 formed nearly as many neurospheres as the control animals, suggesting that the neurosphere-forming multipotent stem cell, which is isolated *in vitro* in the presence of growth factors such as epidermal growth factor, comes from the relatively quiescent stem cell population within the subependyma *in vivo*.

Figures 4a and 4b demonstrate the proliferation and migration of retrovirally-labelled precursor cells in the subependyma in response to EGF-infusion *in vivo* into the lateral ventricle. The animals of Figure 4a and 4b had replication incompetent retroviruses containing the β -galactosidase gene injected into the lateral ventricles of their forebrains. Additionally, the animal of Figure 4b had an osmotic mini-pump filled with 33 μ g/ml EGF implanted at the same site as the injection. Six days later the brains of both animals were fixed and processed for β -gal histochemistry. With the control animal (Fig. 4a) retrovirally labelled cells (open arrow) resided closely to the lateral ventricle wall. The animal that received EGF infusion had many more labelled cells. Additionally the proliferated cells of the EGF-infused animal had migrated away from the lateral ventricle wall (bar represents 200 μ m).

Figure 5 demonstrates that EGF infusion *in vivo* into the lateral ventricle dramatically increases the number of neurospheres formed *in vitro*. Animals were treated with 33 μ g/ml EGF-filled infusion pumps for 6 days prior to sacrifice. Subsequent culturing of the lateral ventricle walls in the presence of 20 ng/ml EGF resulted in a 4-fold increase in the number of neurospheres formed after 9 days *in vitro* as compared to control animals that received infusions of saline for the same 6 days.

Figures 6a and 6b depict the time it takes to reconstitute the number of proliferating cells in the subependyma after a single series of ^3H -thymidine injections (Fig. 6a) and after a second series of ^3H -thymidine injections given 2 days after the first series (Fig. 6b). As shown in Figure 6a, one day after a single

series of injections only 10% of the subependymal cells were proliferating relative to control values (no 3H-thymidine injection). There was a continual increase in the number of proliferating cells over time and by 8 days, the number of proliferating subependymal cells had returned to control values. When a second series of injections was given two days after the first series, as shown in Figure 6b (open circles) the number of stem cells was depleted and the proliferating population was reduced to 50% of control values. When the second series of injections was given four days after the first series (open squares) the number of stem cells which were recruited to repopulate the subependyma had exited from the cell cycle and were no longer proliferating. Hence, they were not killed by the second series of injections on day 4. In this case, the number of proliferating subependymal cells returned to 85% of the control values 8 days after the second series of injections.

Figure 7 shows the relative amounts of tyrosine hydroxylase (TH) mRNA in treated and untreated subventricular zones (SVZs) and in the substantia nigral region (SN) of CD₁ mice, one day and twenty one days after administration of growth factors. CMF = conditioned medium from the rat B49 glial cell line + FGF (25 µg/ml) + heparan sulfate (10 IU/ml). E+F+FBS = EGF (25 µg/ml) + bFGF (25 µg/ml) + heparan sulfate (10 UI/ml) + 25% fetal bovine serum. SAL = saline. NC SVZ = non-cannulated subventricular zone.

Detailed Description of the Invention

Definitions

The term "stem cell" refers to a relatively quiescent undifferentiated cell which is capable of proliferation and giving rise to more stem cells having the ability to generate a large number of progenitor cells that can in turn give rise to differentiated, or differentiable daughter cells.

The term "neural stem cell" refers to multipotent stem cells capable of producing progeny that are capable of differentiating into neurons, astrocytes and oligodendrocytes.

- The term "progenitor cell" refers to an undifferentiated cell derived from a CNS stem cell. The progenitor cell has limited proliferative ability and cannot self-renew. It is committed to a particular path of differentiation and will, under appropriate conditions, eventually differentiate into neurons, astrocytes or
- 5 oligodendrocytes.

The term "oligodendrocyte" refers to a differentiated glial cell which forms the myelin surrounding axons in the central nervous system (CNS). Oligodendrocytes are of the phenotype galactocerebroside (+), myelin basic protein (+), and glial fibrillary acidic protein (-) [GalC(+), MBP(+), GFAP(-)].

- 10 The term "neuron" refers to a differentiated neuronal cell having the phenotype neuron specific enolase (+), neurofilament (+), microtubule associated protein (+), or Tau-1 (+) [NSE(+), NF (+), MAP-2 (+), or Tau-1 (+)].

The term "astrocyte" refers to a differentiated glial cell that is GFAP(+), GalC(-), and MBP(-).

- 15 The term "neurosphere" refers to a cluster of cells derived from neural stem cells and cultured *in vitro*. At least some of the cells are of the nestin (+) phenotype. The cluster is comprised of stem cells and/or progenitor cells and may or may not include differentiated cells.

- The term "precursor cells" refers to the living cells modified or manipulated by the
- 20 methods of the instant invention that are derived from neural stem cells, *in vivo* or *in vitro*, and includes both progenitor and stem cells. *In vitro*, precursor cells typically grow in the form of neurospheres, but may exhibit different growth patterns depending upon culture conditions. Precursor cells are found in the subependyma but are not limited to this CNS region.

- 25 The term "growth factor", refers to a biological factor such as a protein, peptide or other molecule having a growth, proliferative, differentiative, trophic, or regulatory effect (either singly or in combination with other growth factors) on precursor cells.

- Examples of growth factors include acidic and basic fibroblast growth factors (aFGF, bFGF), activin, amphiregulin, the Bcl-2 gene product, bone morphogenic protein (BMP-2), brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), epidermal growth factor (EGF), an EGF-like ligand, glial-derived
- 5 neurotrophic factor (GDNF), heparin-like molecules such as heparan sulphate, insulin-like growth factor (IGF₁), interleukins, macrophage inflammatory proteins (MIP-1 α , MIP-1 β and MIP-2), nerve growth factor (NGF), platelet-derived growth factor (PDGF), retinoic acid, thyrotropin releasing hormone (TRH), transforming growth factors alpha and beta (TGF α , TGF β), and tumor necrosis factor alpha
- 10 (TNF α), and the like.

The term "neurological agent" refers to any biologically active substance useful for the functioning of CNS cells. For example, the term encompasses neurotransmitters, neurotransmitter receptors, growth factors, growth factor receptors, and the like, as well as enzymes used in the synthesis of these agents.

- 15 The term "ventricle" refers to any cavity or passageway within the central nervous system through which cerebral spinal fluid flows. Thus, the term not only encompasses the lateral, third, and fourth ventricles, but also encompasses the central canal and the cerebral aqueduct.

- The term "ventricular tissue" refers to the tissue lining CNS ventricles and includes
- 20 the subependyma which comprises a collection of undifferentiated cells including CNS stem cells and progenitor cells.

- The term "constitutively proliferating population" refers to the population of dividing cells located within the subependyma of the lateral ventricles of the adult mammalian forebrain [as outlined by Smart; *J. Comp. Neurol.* 116:325, (1961)], and
- 25 makes up approximately 33% of the cells in some regions of the subependyma [Morshead and van der Kooy, *J. Neurosci.* 12:249, (1992)].

The term "genetic material" refers to the RNA and DNA that encodes a neurological agent selected from the group consisting of growth factors, growth

factor receptors, neurotransmitters, neurotransmitter receptors, neuropeptides, growth factor synthesizing enzymes, and neurotransmitter synthesizing enzymes. The genetic material is used to infect precursor cells *in vitro* or *in vivo* using genetic modification techniques known in the art.

5 Description of the Preferred Embodiments

In Vitro Isolation and Characterization of Stem Cells From the Adult Mammalian CNS

CNS stem cells have been reported and their potential use described [Reynolds and Weiss, *Science* 255:1707 (1992); Reynolds *et al.*, *J. Neurosci* 12:4565 (1992);

- 10 Reynolds and Weiss, *Restorative Neurology and Neuroscience* 4:208 (1992); Reynolds and Weiss, *Neuronal Cell Death and Repair*, ed. Cuello (1993)].

Additionally, the utility of these cells is described in published PCT applications no. WO 93/01275, WO 94/16718, WO 94/10292, and WO 94/09119. Like stem cells found in other mammalian tissues, the CNS stem cell is capable of self maintenance

- 15 and generating a large number of progeny -- these include neurons, astrocytes and oligodendrocytes.

CNS precursor cells can be isolated and cultured from the adult mammalian CNS by the methods described in Example 2 below and in the Reynolds and Weiss publications and PCT applications referenced above. In brief, the epidermal growth
20 factor (EGF)-responsive stem cell, is grown in a culture medium in the presence of at least one growth factor. The medium is preferably a defined serum-free medium. Growth factors which may be used for inducing proliferation include any trophic factor which allows precursor cells to proliferate, including any molecule which binds to a receptor on the surface of the cell to exert a trophic, or growth-inducing
25 effect on the cell. Preferred growth factors having a proliferative effect include, EGF, amphiregulin, aFGF, bFGF, and TGF α . Various combinations of growth factors can also be used. A preferred combination is EGF with aFGF or bFGF.

- Certain growth factors have a regulatory effect on the proliferation of precursor cells. These growth factors can be used in combination with the above-mentioned
30 proliferation-inducing growth factors to regulate proliferation, for example by

increasing or slowing down proliferation or by altering the phenotypes of the precursor cell progeny. Growth factors that have a regulatory effect on proliferation include heparan sulphate, transforming growth factor beta (TGF β), activin, bone morphogenic protein (BMP-2), ciliary neurotrophic factor (CNTF),
5 retinoic acid, tumor necrosis factor alpha (TNF α), macrophage inflammatory proteins (MIP-1 α , MIP-1 β and MIP-2), nerve growth factor (NGF), platelet derived growth factor (PDGF), interleukins, and the Bcl-2 gene product.

The proliferation inducing growth factor or combination of growth factors induces the proliferation of a CNS stem cell which divides to give rise to a cluster of
10 undifferentiated precursor cells. The clusters of cells are not immunoreactive for GFAP, neurofilament (NF), neuron-specific enolase (NSE) or MBP. However, precursor cells within the cluster are immunoreactive for nestin, an intermediate filament protein found in undifferentiated CNS cells. The nestin marker was characterized by Lehndahl *et al.* [*Cell* 60:585-595 (1990)]. The mature phenotypes
15 associated with the four cell types which may be differentiated from the progeny of the precursor cells are predominantly negative for the nestin phenotype.

In the continued presence of a mitogen such as EGF or the like, precursor cells within the neurosphere continue to divide resulting in an increase in the size of the neurosphere and the number of undifferentiated cells [nestin(+), GFAP(-), NF(-),
20 NSE (-), MBP (-)]. At this stage, the cells are non-adherent and tend to form the free-floating clusters characteristic of neurospheres. However, culture conditions may be varied so that while the precursor cells still express the nestin phenotype, they do not form the characteristic neurospheres. After removal of the mitogen, the cells adhere to the substrate (poly-ornithine-treated plastic or glass), flatten, and
25 begin to differentiate into neurons and glial cells. At this stage the culture medium may contain serum such as 0.5-1.0% fetal bovine serum (FBS). Within 2-3 days, most or all of the precursor cells begin to lose immunoreactivity for nestin and begin to express antigens specific for neurons, astrocytes or oligodendrocytes as indicated by immunoreactivity for MAP-2, GFAP and GalC, respectively.

The identification of neurons is also accomplished using immunoreactivity for neuron-specific enolase (NSE), neurofilament, and the neuron specific protein tau-1.

Because these markers are highly reliable, they will continue to be useful for the primary identification of neurons, however neurons can also be identified based on
5 their specific neurotransmitter phenotype.

Using dual-label immunofluorescence and immunoperoxidase methods, differentiated neurosphere cultures can be analyzed for the expression of neurotransmitters, or in some cases for the enzymes responsible for the neurotransmitter synthesis. Alternatively, *in situ* hybridization histochemistry can
10 be performed using cDNA or RNA probes specific for the peptide neurotransmitter or the neurotransmitter synthesizing enzyme mRNAs. These techniques can be combined with immunocytochemical methods to enhance the identification of specific phenotypes. If necessary, the antibodies and molecular probes discussed above can be applied to western and northern blot procedures respectively to aid in
15 the cell identification.

Cells that do not express intermediate filaments specific for neurons or for astrocytes, begin to express markers specific for oligodendrocytes in a correct temporal fashion. That is, the cells first become immunoreactive for O4 (a cell surface antigen), galactocerebroside (GalC, a myelin glycolipid) and finally, myelin
20 basic protein (MBP). These cells also possess a characteristic oligodendrocyte morphology.

CNS stem cells have been isolated from a variety of adult CNS regions, including the conus medullaris (see Fig. 1a-1c), cervical and thoracic spinal cord, brain stem, and hypothalamus. In each of these cases the isolated CNS stem cell exhibits self-
25 maintenance and generates a large number of progeny which include neurons, astrocytes and oligodendrocytes. Thus stem cells are present in multiple regions of the adult mammalian CNS.

Characterization and Manipulation of Stem Cells from the Adult Mammalian CNS In Vivo

- The techniques that are described above to isolate, proliferate, and differentiate, CNS stem cells *in vitro* can be adapted to *in vivo* techniques, as described below, to achieve similar results. Such *in vivo* manipulation and modification of these cells allows cells lost, due to injury or disease, to be endogenously replaced, thus
- 5 obviating the need for transplanting foreign cells into a patient. Additionally, the cells can be modified or genetically engineered *in vivo* so that they express various biological agents useful in the treatment of neurological disorders.

- Normally, the adult mammalian CNS is mitotically quiescent *in vivo* with the exception of the subependymal region lining the lateral ventricles in the forebrain.
- 10 This region contains a subpopulation of constitutively proliferating cells with a cell cycle time of 12.7 hours. BrdU and retroviral labelling of the proliferating cells reveal that none of the newly generated cells differentiate into mature neurons or glia nor do they migrate into other CNS regions (Morshead and Van der Kooy, *supra*).
- 15 The continual proliferation and maintenance of a constant number of cells within the subependyma is explained by two mechanisms. The death of one of the daughter cells after each division maintains the proliferating population at a constant number. The constitutively dividing population eventually dies out and a subpopulation of relatively quiescent cells within the subependyma is able to
- 20 repopulate the constitutively dividing population. This stem cell-like mode of maintaining the proliferative subependymal population is analogous to other tissues where cells have a short life span and are repopulated by a subpopulation of relatively quiescent cells referred to as stem cells.

- As detailed in Example 1, experiments utilizing retrovirus infection of these
- 25 proliferating cells *in vivo* and subsequent β -galactosidase (β -gal) reporter gene expression as a non-diluting marker show that with increasing adult mice survival times (of up to 28 days post retrovirus infection) there is a progressive loss of β -gal positive subependymal cells. Relative to 1 day survival animals, 6 days following retrovirus injection there is a 45% loss of β -gal positive cells and 28 days following
- 30 retrovirus infection there is a 97% loss. Using nested polymerase chain reaction

(PCR) to identify single cells containing retroviral DNA it was determined that the loss of β -gal expressing cells is due to the loss of the retrovirally infected cells through cell death, not due to the turn-off of β -gal expression.

Intraperitoneal injections of BrdU (a thymidine analog that is incorporated into the DNA of dividing cells) reveal that 33% of the cells within some regions of the subependyma make up the normally dividing population (see Example 9 below). The number of BrdU labelled cells decreases over time. By 30 days after BrdU labelling, only 3% of the dividing cells are still labelled. The heavy labelling of a small number of cells 30 days after BrdU injections demonstrates that the labelled cells were dividing at the time of the injections and suggests that they were relatively quiescent for the 30 day period. This indicates that these cells are stem cells rather than cells of the constitutively proliferating population.

The above two examples support the hypothesis that the maintenance of the constant number of proliferating subependymal cells seen throughout adult life requires the presence of a relatively quiescent stem cell that proliferates sporadically to replenish the constitutively proliferating population and to self-renew.

As detailed in Example 5, the constitutively dividing subependymal cells can be killed off by injecting high doses of radioactive thymidine for the duration of the cell cycle at intervals less than S-phase duration. At one day post-kill the proliferating population is 10% of controls and by 8 days the proliferating population is back to control levels. If the replenished population is due to the recruitment of normally quiescent cells into the proliferative mode, then a second kill at the time that stem cells are generating progeny to repopulate the subependyma should alter the number of cells within the constitutively proliferating population. When a second kill is done 2 days after the initial kill, 8 days later the constitutively proliferating population is only 45% of the control values (animals receiving no thymidine kill treatment) or animals that received only one kill at day 0 (the time of the first kill) (see Fig. 6b). The reduction in the number of proliferative cells in the subependyma is maintained at 63% even at 31 days after the second kill. When a second kill is done on day 4, the proliferating population

returns to 85% of control values 8 days later. These results suggest that the normally quiescent stem cell is recruited into the proliferative mode within the first two days after the initial kill and that by 4 days the stem cell no longer needs to be recruited to repopulate the subependyma (see Fig. 2).

- 5 As detailed in Example 6 below, an experiment was performed to determine whether the *in vitro* stem cell is derived from the constitutively proliferating population or from the quiescent population. Animals were treated in one of the following ways:

- | | | |
|----|--|-----------------|
| | Group 1. | Control |
| 10 | High doses of radioactive thymidine were given on: | |
| | Group 2. | day 0 |
| | Group 3. | day 0 and day 2 |
| | Group 4. | day 0 and day 4 |

- Following the last injection animals were killed and stem cells isolated from the striatum (including the subependymal region) via the methods described in Example 2 below.

In groups 2-4 the constitutively proliferating population was killed. In group 3 stem cells that are recruited into the cell cycle to repopulate the subependymal proliferating cells were also killed.

- 20 Number of Neurospheres produced *in vitro*:

- | | |
|----------|----------------|
| Group 1. | 100% (Control) |
| Group 2. | 100% |
| Group 3. | 45% |
| Group 4. | 85% |

- 25 These results demonstrate that when you eliminate nearly all of the constitutively proliferating cells in the subependyma this does not affect the number of stem cells that can be isolated and proliferated *in vitro* (group 1 vs. group 2 and 4). However, when the normally quiescent cells are killed when they are recruited to repopulate the subependyma (as with group 3) the number of stem cells that can be isolated *in*

vitro is significantly reduced (group 3 vs. group 1 and 2). By 4 days after the first kill most of the stem cells themselves are no longer turning over and as a result are not killed by the second series of tritiated thymidine injections (hence, only a 15% reduction [group 4] compared to 55% reduction [group 3]).

- 5 The above results demonstrate that *in vitro* stem cells are derived from the quiescent population of subependymal cells *in vivo* (see Fig. 3). This also explains why stem cells can be derived from CNS ventricular regions, other than the forebrain, which do not have the subpopulation of constitutively proliferating cells. Thus, having determined the relationship between the constitutively proliferating
- 10 population of subependymal cells and the relatively quiescent stem cells of the lateral ventricles, one can take advantage of the characteristics of these cell populations to more effectively manipulate them *in vivo*. Such techniques allow the use and manipulation of endogenous cells for the treatment of a variety of neurological disorders. Some factors that influence proliferation and differentiation
- 15 of the cells *in vitro* also achieve the same effects *in vivo*. Thus, for example, cells can be manipulated *in situ* by the administration of growth factors and combinations of growth factors that result in specified outcomes as determined by *in vitro* studies. For example, the *in vitro* differentiation methods disclosed in WO 94/10292 in which cells can be induced to follow a particular differentiative pathway, may be
- 20 modified using the methods described herein to achieve similar results *in vivo*. The growth factors can be administered to a ventricle by stereotactic injection, implantation of an osmotic pump, or any other suitable method.

The quiescent neural stem cells are located throughout the CNS near ventricular regions. Within the forebrain are the lateral (first and second) ventricles. The third

25 ventricle is a cavity of the lower part of the forebrain. The cavity of the midbrain is the tubular shaped cerebral aqueduct and connects the third ventricle with the cavity within the hindbrain, the fourth ventricle. The central canal is the passageway for cerebral spinal fluid within the spinal cord.

The fact that CNS stem cells are located in the tissues lining ventricles offers

30 several advantages for the modification and manipulation of these cells *in situ* and

- the ultimate treatment of various neurological diseases, disorders, and injury that affect different regions of the CNS. Therapy for these can be tailored accordingly so that stem cells surrounding ventricles near the affected region would be manipulated or modified *in situ* using the methods described herein. The
- 5 ventricular system is found in nearly all brain regions and thus allows easier access to the affected areas. If one wants to modify the stem cells by exposing them to a composition comprising a growth factor or a viral vector, it is relatively easy to implant a device that administers the composition to the ventricle. For example, a cannula attached to an osmotic pump may be used to deliver the composition.
- 10 Alternatively, the composition may be injected directly into the ventricles. This would allow the migration of the CNS stem cell progeny into regions which have been damaged as a result of injury or disease. Furthermore, the close proximity of the ventricles to many brain regions would allow for the diffusion of a secreted neurological agent by the stem cells or their progeny.
- 15 For treatment of Huntington's Disease, Alzheimer's Disease, Parkinson's Disease, and other neurological disorders affecting primarily the forebrain, growth factors or other neurological agents would be delivered to the ventricles of the forebrain to affect *in situ* modification or manipulation of the stem cells. For example, Parkinson's disease is the result of low levels of dopamine in the brain, particularly
- 20 the striatum. It would be advantageous to induce a patient's own quiescent stem cells to begin to divide *in vivo* and to induce the progeny of these cells to differentiate into dopaminergic cells in the affected region of the striatum, thus locally raising the levels of dopamine. Normally the cell bodies of dopaminergic neurons are located in the substantia nigra and adjacent regions of the
- 25 mesencephalon, with the axons projecting to the striatum. Prior art pertaining to the induction of dopaminergic neurons in the brain focusses on manipulations of the mesencephalic tissue. Prior art methods for treating Parkinson's disease usually involves the use of the drug L-Dopa, to raise dopamine levels in the striatum. However, there are disadvantages with this treatment including drug tolerance and
- 30 side effects. Also, embryonic tissues that produce dopamine have been transplanted into the striatum of human Parkinsonian patients with reasonable success. However, in addition to being a controversial method of treatment, there are risks

associated with implantation of foreign tissue including tissue rejection and infection.

The methods and compositions of the present invention provide an alternative to the use of drugs and the controversial use of embryonic tissue for treatment of

5 Parkinson's disease. The level of dopamine cells in the striatum is increased by the administration of a composition comprising growth factors to the lateral ventricle.

A particularly preferred composition comprises a combination of EGF, bFGF, and heparan sulphate. The composition preferably also comprises serum. After administration of this composition, there is a significant increase in the transcription

10 of messenger RNA (mRNA) for tyrosine hydroxylase (TH) (a marker for dopamine cells) in the subventricular region of the striatum, an area which normally does not contain dopaminergic cell bodies. These methods and results are described in detail in Example 11. As detailed in Example 12, dual labelling tissue to show the distribution of BrdU+ and TH+ cells indicates that, in response to the *in vivo*

15 administration of growth factors, TH+ cell bodies occur in striatal tissue. Many of these newly generated TH+ cells are also BrdU+.

For the treatment of multiple sclerosis and other demyelinating or hypomyelinating disorders, and for the treatment of Amyotrophic Lateral Sclerosis or other motor neuron diseases, growth factors or other neurological agents would be delivered to

20 the central canal. Other diseases and disorders which would be treated by the methods of the present invention are disclosed in PCT application WO 93/01275.

In addition to treating CNS tissue immediately surrounding a ventricle, a viral vector, DNA, growth factor, or other neurological agent can be easily administered to the lumbar cistern for circulation throughout the CNS.

25 Under normal conditions subependymal precursors do not differentiate or migrate, rather, their fate appears to be cell death after an undefined number of cell divisions (Morshead and Van der Kooy, *supra*). This explanation is also supported by PCR evidence, as described above. Injection of growth factors into the lateral ventricle alters this fate. As described in more detail in Example 1 below, retroviruses were

injected into the lateral ventricles for six consecutive days. Implanting cannulae attached to EGF-filled osmotic pumps into the lateral ventricles on the same day as (and 1 or 6 days following) retrovirus injection results in an increase in the total number of RV- β -gal labelled cells 6 days later (from an average of 20 cells/brain to 150 cells/brain).

It is known from the PCR experiments described above that 6 days following retroviral injection no cells exist that contain non-expressed retroviral DNA. Thus these results indicate that the EGF-induced increase in β -gal positive cell number is due to the expansion of the clone size of the retrovirally labelled constitutively proliferative population. It is also possible that part of this increase is due to the activation by EGF of a relatively quiescent stem cell.

Interestingly, this expansion of the number of β -gal labelled cells is accompanied by the migration of these cells away from the subependymal medially and laterally (and possibly rostrally and caudally) up to a distance of approximately 400 μ m (see Fig. 4), with subsequent differentiation. Thus, infusion of EGF or similar growth factors induces the proliferation, migration and differentiation of neural stem cells and progenitor cells *in vivo*, and can be used therapeutically to replace neural cells lost due to injury or disease. In a preferred embodiment EGF and FGF are administered together or sequentially.

The normal fate of the constitutively proliferating cell population (i.e. cell death) can be altered by administering Bcl-2 or genetically modifying the cells with the bcl-2 gene. The gene product is known to prevent programmed cell death (apoptosis) in a variety of cell types. Similar to the EGF experiments, a clonal expansion of the constitutively proliferating cell population is achieved.

The *in vivo* techniques described herein can be used to genetically modify CNS stem cells and progenitor cells. Any useful genetic modification of the cells is within the scope of the present invention. For example, the cells may be modified to produce or increase production of a neurological agent such as a neurotransmitter, growth factor, or the like. The genetic modification is performed

either by infection of the cells lining CNS ventricular regions with recombinant retroviruses or transfection using methods known in the art [see Maniatis *et al.*, *Molecular Cloning: A Laboratory Manual*, Cold Spring Harbor Laboratory, N.Y. (1982)]. Any method of genetic modification, now known or later developed can
5 be used. With direct DNA transfection, cells could be modified by particle bombardment, receptor mediated delivery, and cationic liposomes. When chimeric gene constructs are used, they generally will contain viral, for example retroviral long terminal repeat (LTR), simian virus 40 (SV40), cytomegalovirus (CMV); or mammalian cell-specific promoters such as tyrosine hydroxylase (TH), dopamine β -
10 hydroxylase (DBH), phenylethanolamine N-methyltransferase (PNMT), choline acetyltransferase (ChAT), glial fibrillary acidic protein (GFAP), neuron-specific enolase (NSE), the neurofilament (NF) proteins (NF-L, NF-M, NF-H, and the like) that direct the expression of the structural genes encoding the desired protein.

If a retroviral construct is to be used to genetically modify normally quiescent stem
15 cells, then it is preferable to induce the proliferation of these cells using the methods described herein. For example, an osmotic infusion pump could be used to deliver growth factors to the central canal several days prior to infection with the retrovirus. This assures that there will be actively dividing neural stem cells which are susceptible to infection with the retrovirus.

20 When the genetic modification is for the production of a biologically active substance, the substance will generally be one that is useful for the treatment of a given CNS disorder. For example, it may be desired to genetically modify cells so they secrete a certain growth factor product. Growth factor products useful in the treatment of CNS disorders include, but are not limited to, nerve growth factor
25 (NGF), brain-derived neurotrophic factor (BDNF), the neurotrophins (NT-3, NT-4/NT-5), ciliary neurotrophic factor (CNTF) and other cytokines, amphiregulin, bFGF, aFGF, EGF, TGF α , TGF β , PDGF, IGFs, and the interleukins.

Cells can also be modified *in vivo* to express a certain growth factor receptor (r) including, but not limited to, p75 low affinity NGFr, CNTFr, the *trk* family of
30 neurotrophin receptors (*trkA*, *trkB*, *trkC*), EGFr, FGFr, and amphiregulin receptors.

- Cells can be engineered to produce various neurotransmitters or their receptors such as serotonin, L-dopa, dopamine, norepinephrine, epinephrine, tachykinin, substance-P, endorphin, enkephalin, histamine, N-methyl D-aspartate (NMDA), glycine, glutamate, γ -amino butyric acid (GABA), acetylcholine, and the like. Useful
- 5 neurotransmitter-synthesizing genes include TH, dopa decarboxylase (DDC), DBH, PNMT, glutamic acid decarboxylase (GAD), tryptophan hydroxylase, ChAT, and histidine decarboxylase. Genes that encode for various neuropeptides, which may prove useful in the treatment of CNS disorders, include substance-P, neuropeptide-Y (NP-Y), enkephalin, vasopressin, vasoactive intestinal peptide (VIP), glucagon,
- 10 bombesin, cholecystokinin (CCK), somatostatin, calcitonin gene-related peptide (CGRP), and the like.

Improvement to In Vitro Techniques for Proliferation of CNS Stem Cells

- The absolute yield of the number of precursor cells isolated *in vitro* from the mammalian CNS can be increased dramatically by injecting a growth factor or
- 15 combination of growth factors, for example EGF, FGF, or EGF and FGF together, into the ventricles *in situ* as described above. As detailed in Example 10 below, 6 days after infusion of EGF into the lateral ventricle of a mouse forebrain, the walls of the ventricle were removed and the stem cells harvested. Infusion of EGF into the lateral ventricle increased the efficiency of the yield of stem cells that
- 20 proliferated to form neurospheres.

- This technical improvement of *in vitro* technology for the proliferation of CNS stem cells should prove invaluable when stem cells are to be harvested for later transplantation back into a patient, thereby making the initial surgery 1) less traumatic because less tissue would have to be removed and 2) more efficient
- 25 because a greater yield of stem cells per surgery would proliferate *in vitro*. Additionally, the patient's stem cells, once they have proliferated *in vitro*, could also be genetically modified *in vitro* using the techniques described in PCT application WO 94/16718. The *in vitro* genetic modification may be more desirable in certain circumstances than *in situ* techniques when more control over the
- 30 infection with the genetic material is required.

In order that the invention described herein may be more fully understood, the following examples are set forth. It should be understood that these examples are for illustrative purposes only and are not to be construed as limiting the scope of the invention in any manner.

5

EXAMPLES

Example 1

A replication incompetent retrovirus containing the β -galactosidase gene [as described in Walsh and Cepko, *Science* 241:1342, (1988)] was injected into the forebrain lateral ventricles of CD1 adult male mice (25-30 g from Charles River).

- 10 The injected retrovirus was harvested from the BAG cell line (ATCC CRL-9560) according to the method of Walsh and Cepko (*supra*). Mice were anesthetized using 65 mg/kg, i.p. sodium pentobarbital. Unilateral stereotactic injections of 0.2-1.0 μ l of retrovirus were injected into the lateral ventricle using a 1 μ l Hamilton syringe. The coordinates for injection were AP +4.2 mm anterior to lambda, L \pm 15 0.7 mm, and DV -2.3 mm below dura, with the mouth bar at -2mm below the interaural line.

- On the same day as, one day, or six days following the retrovirus injection, an infusion cannulae attached to a 0.5 μ l/hour ALZET osmotic mini-pumps filled with 3.3 - 330 μ g/ml of EGF were surgically implanted into the lateral ventricles at the 20 identical stereotactic coordinates as stated above. The infusion cannula kits were obtained from ALZA. The infusion cannulae were cut to 2.7 mm below the pedestal. The pumps were secured to the mouse skull by use of acrylic cement and a skull screw contralateral and caudal to the injection site. The osmotic mini-pump was situated subcutaneously under and behind the armpit of the left front paw and 25 connected to the infusion cannula by the means of polyethylene tubing.

Six days following initiation of EGF infusion the animals were sacrificed with an overdose of sodium pentobarbital. Mice were transcardially perfused with 2% buffered paraformaldehyde, and the brains were excised and post fixed overnight with 20% sucrose in 2% buffered paraformaldehyde. Coronal slices were prepared

with -20 celsius cryostat sectioning at 30 μ m. Slices were developed for β -gal histochemistry as per Morshead and Van der Kooy (*supra*).

Under these conditions, regardless of the day post retrovirus injection, infusion of EGF resulted in an expansion of the population of β -gal labelled cells from an average of 20 cells per brain up to an average of 150 cells per brain and the migration of these cells away from the lining of the lateral ventricles (see Fig. 4). Infusion of basic fibroblast growth factor (bFGF), 33 μ g/ml resulted in an increase in the number of β -gal labelled cells, but this increase was not accompanied by any additional migration. Infusion of EGF and FGF together resulted in an even greater expansion of the population of β -gal labelled cells from 20 cells per brain to an average of 350 cells per brain.

These results indicate that FGF may be a survival factor for relatively quiescent stem cells in the subependyma layer, whereas EGF may act as a survival factor for the normally dying progeny of the constitutively proliferating population. The synergistic increase in β -galactosidase cell number when EGF and FGF are infused together further reflects the direct association between the relatively quiescent stem cell and the constitutively proliferating progenitor cell.

Example 2

The striata, including the subependymal region, of female, pathogen-free CD1 albino mice [3 to 18 month old; Charles River (CF1 and CF2 strains yielded identical results)] were dissected and hand cut with scissors into 1-mm coronal sections and transferred into artificial cerebrospinal fluid (aCSF) containing 124 mM NaCl, 5 mM KCl, 1.3 mM $MgCl_2$, 2 mM $CaCl_2$, 26 mM $NaHCO_3$, and 10 mM D-glucose (pH 7.35, approx. 180 mOsmol), aerated with 95% O_2 - 5% CO_2 at room temperature. After 15 minutes the tissue sections were transferred to a spinner flask (Bellco Glass) with a magnetic stirrer filled with low- Ca^{2+} aCSF containing 124 mM NaCl, 5 mM KCl, 3.2 mM $MgCl_2$, 0.1 mM $CaCl_2$, 26 mM $NaHCO_3$, and 10 mM D-glucose (pH 7.35, approx. 180 mOsmol), aerated with 95% O_2 - 5% CO_2 at 32 to 35° C., containing 1.33 mg/ml of trypsin (9000 BAEE units/mg), 0.67 mg/ml of hyaluronidase (2000 units/mg) and 0.2 mg/ml of kynurenic acid. After 90

minutes, tissue sections were transferred to normal aCSF for 5 minutes prior to trituration. Tissue was transferred to DMEM/F-12 (A:1, Gibco) medium containing 0.7 mg/ml ovomucoid (Sigma) and triturated mechanically with a fire-narrowed pasteur pipet. Cells were plated (1000 viable cells per plate) in noncoated 35 mm

5 culture dishes (Costar) containing serum-free medium [this included a defined hormone mix and salt mixture that included insulin (25 µg/ml), transferrin (100 µg/ml), progesterone (20 nM), putrescine (60µM), and selenium chloride (30 nM); glucose (0.6%); glutamine (2 mM); sodium bicarbonate (3 mM); and HEPES buffer (5 mM)] and EGF [20 ng/ml, purified from mouse sub-maxillary gland

10 (Collaborative Research)] or human recombinant (Gibco/BRL). Cells were allowed to settle for 3-10 minutes after which the medium was aspirated away and fresh DMEM/F-12/hormone mix/EGF was added. After 5-10 days *in vitro* the number of spheres (neurospheres) were counted in each 35 mm dish.

Example 3.

15 A retroviral construct containing the human bcl-2 gene and the β-galactosidase gene is microinjected into the adult mouse lateral ventricle. A control mouse is injected with a retroviral construct containing only the β-galactosidase gene. One of the two progeny of each of the constitutively proliferating subependymal cells of the adult lateral ventricle normally dies within a few hours after division. The bcl-2 gene

20 product prevents the programmed death of cells in several other tissues. In the adult subependyma, single cells infected with both the β-galactosidase and bcl-2 genes are marked by expression of both these gene products. These cells are identified in brain tissue slices with antibodies specific to β-galactosidase and human Bcl-2. Proliferating infected subependymal cells so infected produce larger

25 numbers of cells per clone relative to the control. Thus, Bcl-2 induces the survival of the one normally dying progeny of each division of a constitutively proliferating adult subependymal cell. Moreover, the bcl-2 infected progeny migrate out into striatal and septal tissue to produce new neurons and glia. This indicates that EGF and Bcl-2 act as a survival factors for the normally dying progeny of constitutively

30 proliferating adult subependymal cells which generate new neurons and glia *in vivo*.

Example 4.

A retroviral construct containing the nerve growth factor gene is microinjected (as was the construct in Example 1) to infect the constitutively proliferating adult subependymal cells of the lateral ventricle. Thus, these cells are used to produce an endogenous growth factor in the adult brain. Levels of nerve growth factor
5 produced by the transfected cells are measured directly by radioimmunoassay and (from a direct functional assay) by rescue of basal forebrain cholinergic neurons *in vivo* after axotomy injury in the model developed by Gage and collaborators (P.N.A.S. 83:9231, 1986).

Example 5.

10 Adult male CD1 mice received a series of intraperitoneal injections of 3H-thymidine (0.8 ml per injection, specific activity 45-55 mCi/mmol, ICN Biomedical) on day 0 (3 injections, 1 every 4 hours) in order to kill the constitutively proliferating subependymal cells. On day 0.5, 1, 2, 4, 6, 8 or 12, animals received 2 BrdU injections 1 hour apart (see Example 9) and were
15 sacrificed 0.5 hour after the last injection.

It was observed that 10% of the cells were proliferating on day 1 post-kill, and by 8 days the number of proliferating cells had reached 85% (see Fig. 6a), which was not statistically significantly different from control values. Animals were sacrificed and the brains were removed and processed as described in Example 9.

20 In a second group of animals, 3H-thymidine injections were given on day 0 (3 injections, 1 every 4 hours), followed by an identical series of injections on day 2 or 4. Animals were allowed to survive for 8 days following the second series of injections (days 9, 10 and 12 respectively) at which time they received 2 injections of BrdU and were sacrificed 0.5 hours later. Animals were sacrificed and the
25 brains were removed and processed as described in Example 9.

After the second series of injections on day 2 only 45% of the proliferating population had returned relative to control values. This indicates that the second series of injections given on day 2 had killed the stem cells as they were recruited to the proliferating mode (see Fig. 6b). The second series of injections given on

day 4 resulted in a return to control values by day 8 suggesting that by this time, the stem cells were no longer proliferating and hence were not killed by the day 4 series of injections (Fig. 6b).

Example 6.

- 5 Adult male CD1 mice were divided into 4 groups. Group A animals received a series of 3H-thymidine injections on day 0 (3 injections, 1 every 4 hours). Animals in groups B and C received a series of 3H-thymidine injections on day 0 followed by a second series of injections on day 2 or 4. Group D animals received injections of physiological saline instead of 3H-thymidine over the same time course as group
- 10 A. Animals from all groups were sacrificed by cervical dislocation 16-20 hours following the last series of injections. Brains were removed and the subependyma surrounding the lateral ventricles in the forebrain were dissected and cultured as described in Example 2 in order to assess the number of spheres that formed following each of the injection paradigms. The cells from each brain were plated
- 15 into two 35 mm wells. At 6 and 8 days *in vitro*, the total number of spheres was counted in each of the 35 mm wells (see Fig. 3).

- Control animals that received a series of saline injections formed the same number of spheres as animals that received 3H-thymidine on day 0 (which kills the normally proliferating subependymal cells). This indicates that the constitutively
- 20 proliferating subependymal cells are not the source of stem cells isolated *in vitro*. Animals that received a second series of injections on day 2 formed 45% the number of spheres (similar to the number of proliferating subependymal cells observed *in vivo*). When a second series of injections was done on day 4, the number of spheres formed *in vitro* was not significantly different from control
- 25 values, again correlating with the *in vivo* findings. Taken together, this data indicates that the multipotent spheres, which are isolated *in vitro* in the presence of EGF, are formed from the relatively quiescent stem cell population within the subependyma *in vivo*.

Example 7.

A retroviral construct containing the β -galactosidase gene is microinjected (as in Example 1) into the III ventricle of the diencephalon, IV ventricle of the brain stem and central canal of the spinal cord. Minipumps containing EGF and FGF are then used to continuously administer growth factors for six days (as in Example 1) into the same portion of the ventricular system that the retroviral construct was administered. This produces an increase in the number of β -galactosidase producing cells which survive and migrate out into the tissue near the III ventricle, IV ventricle and central canal of the spinal cord forming new neurons and glia.

Example 8.

A retroviral construct containing the tyrosine hydroxylase (TH) gene as well as the β -galactosidase gene is microinjected into the adult lateral ventricle as in Example 1. Minipumps containing EGF, FGF, or EGF and FGF together are then used to continuously administer the growth factor(s) into the lateral ventricle for 6 days as in Example 1. As the infected subependymal cells migrate out into the striatum they differentiate into neuronal cells that produce dopamine as measured directly by immunofluorescence with an antibody and (from a direct functional assay) by the ability to overcome the rotational bias produced by unilateral 6-hydroxydopamine lesions.

Example 9.

Adult male CD1 mice (25-30 g, Charles River) were injected intraperitoneally (i.p.) with bromodeoxyuridine (BrdU, Sigma, 65 mg/kg) every 2 hours for a total of 5 injections in order to label all of the constitutively proliferating cells in the subependyma lining the lateral ventricles in the forebrain. One month later, animals were sacrificed with an overdose of sodium pentobarbital and transcordially perfused using 4% paraformaldehyde. The brains were removed and post-fixed overnight in 4% paraformaldehyde with 20% sucrose. Brain sections were cut on a cryostat (30 μ m) and collected in a washing buffer [0.1 M phosphate buffered saline (PBS) pH 7.2 with 1% normal horse serum and 0.3% Triton X-100]. Sections were incubated in 1M HCl at 60° C. for 0.5 hours then washed 3 times (10 minutes each) in washing buffer. Following the final wash, sections were incubated in anti-BrdU (Becton Dickinson, 1:25) for 45 hours at 4° C. After incubation in the

primary antibody, sections were washed 3 times and incubated for 1 hours in biotinylated horse-anti-mouse secondary antibody (Dimension Lab, 1:50) at room temperature followed by another 3 washes. The sections were then incubated for 1 hour in avidin conjugated FITC (Dimension Lab, 1:50) at room temperature and
5 washed a final 3 times. Sections were mounted on gelatin coated slides, air-dried and coverslipped with Fluoromount. Slides were examined for BrdU positive cells using a NIKON fluorescent microscope. The number of BrdU positive cells was counted within the subependyma surrounding the lateral ventricles in 8 samples in sections between the closing of the corpus callosum rostrally and the crossing of the
10 anterior commissure caudally. It was found that 31 days following the series of BrdU injections, 3% of the subependymal cells were still labeled compared to control animals sacrificed immediately following the series of injections (control 100%).

Example 10

15 EGF pumps were implanted as described in Example 1. Animals were sacrificed by cervical dislocation 6 days after the pump was implanted. Brains were removed and stem cells isolated and counted as described in Example 2.

As shown in Figure 5, animals infused with EGF into the lateral ventricles for 6 days prior to sacrifice and brain culturing had 4 times as many spheres forming
20 after 9 days *in vitro* compared to control animals which received saline pumps for the same 6 day period. Thus, infusing EGF into the lateral ventricles *in vivo* prior to removal of precursor cells greatly increases the yield of stem cells which proliferate and form neurospheres *in vitro*.

Example 11.

25 Adult male CD₁ mice were anesthetized and placed in a stereotaxic apparatus. A cannula, attached to an ALZET minipump, was implanted into a lateral ventricle of each animal. The minipumps were subcutaneously implanted and were used to deliver (a) conditioned medium (from the rat B49 glial cell line, obtained from D Schubert, Salk Institute) plus bFGF (R&D Systems, 25 µg/ml) plus heparan sulfate
30 (Sigma, 10 IU/ml) (CMF) or (b) EGF (Chiron, 25 µg/ml) plus bFGF (25 µg/ml)

plus heparan sulfate (10 IU/ml) plus 25% fetal bovine serum (E+F+FBS) or (c) sterile saline solution (SAL) as a control, into the lateral ventricles. Once batch of animals was sacrificed one day after completion of the delivery regimen and the others were sacrificed twenty days later. The subventricular zones (SVZs) of these mice were dissected out, separating the cannulated, and therefore treated, side from the non-cannulated control sides. The substantia nigra (SN) region of these mice were also recovered. Total RNA was extracted from these tissues using the guanidium thiocyanate acid phenol method [Chomzynski and Sacchi, *Anal. Biochem.* 162: 156-159, (1987)]. The RNA was then reverse transcribed to produce cDNA. These cDNAs were subject to polymerase chain reaction (PCR) using primers designed to bracket a 254 nucleotide region of the tyrosine hydroxylase (TH) messenger RNA (mRNA) and thermal cycling conditions favoring quantitative amplification. The PCR products were electrophoresed on a 2% agarose gel and then capillary blotted onto a positively charged nylon membrane. Radioactively labelled cDNA probe to TH was hybridized to the filter and detected by autoradiography. The autoradiograph was scanned and analyzed by densitometry to obtain relative levels of mRNA for TH in the SVZs of the cannulated sides in response to the treatments in the non-cannulated control SVZs and in the SN. The results are depicted in the bar graph of Figure 7. In animals analyzed one day after treatment, the administration of E+F+FBS produced an eleven-fold increase in the level of TH mRNA in the SVZ compared to that observed in response to CMF, which in turn was more than twice the level seen with SAL. Twenty one days after treatment, the amount of TH mRNA detected in response to treatment with E+F+FBS was approximately the same as that detected after one day, while CMF and SAL treated SVZs had TH mRNA levels which were below detectable limits and were indistinguishable from the non-cannulated SVZ controls. Under all treatments, the SN had measurable amounts of TH mRNA.

Example 12

Male CD₁ mice (Charles River, approximately 4 to 6 weeks old) were given intraperitoneal injections of BrdU (Sigma, 120mg/kg) at 2 hour intervals over a 24 hour period, in order to label mitotically active cells. A cannula attached to an ALZET minipump was then implanted unilaterally into a lateral ventricle of each

animal in order to deliver compositions a-c (CMF, E+F+FBS, or sterile saline) described in Example 11.

Animals were sacrificed 24 hours after the administration of growth factors using a lethal dose of pentobarbital anesthetic. The animals were then perfused through the heart with 10 ml of ice cold 4% paraformaldehyde solution. The brains were removed and tissue in the region extending from the olfactory bulb to the third ventricle, including the striatum, was dissected out and stored overnight at 4°C in a 30% sucrose/4% paraformaldehyde solution. The tissue was then frozen on dry ice and kept at -70°C until processed. 30µm coronal sections were cut using a cryostat and the sections were placed in 12 well porcelain dishes, to which 400 µl of PBS had been added. Sections were rinsed with fresh PBS and incubated overnight with the following primary antibodies: anti-TH (rabbit polyclonal, 1:1000, Eugene Tech International Inc.; or 1:100, Pel-freeze) and mouse anti-BrdU (1:55, Amersham), prepared in PBS/10% normal goat serum/0.3 Triton X-100. Following three rinses in PBS, goat anti-rabbit rhodamine and goat anti-mouse fluorescein (Jackson) were applied in PBS for 50 minutes at room temperature. Sections were then washed three times (10 minutes each) in PBS, placed on glass slides, dried and then coverslipped using Fluorsave (Calbiochem #345789).

The location of dopaminergic neurons was determined by mapping the location of TH-immunoreactive (TH+) cells, or TH+ and BrdU+ cells in relation to the ventricles. In response to saline injections made into the lateral ventricles, the normal population of TH+ fibers were detected in the striatum but no TH+ cell bodies were detected in this region. CMF treatment resulted in the detection of TH+ cell bodies, in addition to the normal population of TH+ fibers, in the striatum and in the region of the third ventricle. E+F+FBS treatment had the most profound effect resulting in the detection of the most TH+ cell bodies. Several of the TH+ cell bodies were also BrdU positive.

Example 13

The 6-hydroxy-dopamine (6-OHDA) lesion rat model of Parkinson's disease is used to measure the effects of administering various combinations of growth factors to

the lateral ventricle. Unilateral 6-OHDA lesions are performed in the rat model and rotation behavior is observed. Minipumps are subcutaneously implanted into the animals as described in Example 11. EGF (Chiron, 25 µg/ml) plus bFGF (25 µg/ml) plus heparan sulfate (10 IU/ml) plus 25% fetal bovine serum is continuously administered to the lateral ventricle. Saline is administered to control animals. The ability to overcome the rotational bias produced by the unilateral 6-OHDA lesions is observed.

Example 14.

Adult male CD₁ albino mice (30-35g) from Charles River were anaesthetized with sodium pentobarbital (0.40 mL of a 10% solution) and placed in a stereotaxic apparatus. The dorsal aspect of the skull was exposed with a longitudinal incision. Cannulas were inserted into the fourth ventricle (stereotaxic coordinates A/P -7.0, L ± 0.3 D/V -5.8), cerebral aqueduct (A/P -4.8 L ± D/V -2.6), or central canal (D/V -1.5). The cannulae were attached with sterile tubing to subcutaneous positioned ALZET osmotic mini-pumps containing 25 µg/mL EGF (Becton 40001) and/or 25 µg/mL bFGF (R&D Systems 233-FB). Pumps containing sterile saline plus 0.1% mouse albumin (Sigma A3134) were used as controls. The incisions were closed with dental cement.

Six days following surgery mice were injected with 0.15 mL BrdU (Sigma B5002); 18 mg/mL in 0.007% NaOH/0.1M PBS) every 2 hours for 8 hours. They were killed 0.5 hours after the last injection with an anaesthetic overdose, and transcardially perfused with 10 mL of ice-cold sterile saline followed by 10mL of ice-cold Bouin's fixative (5% glacial acetic acid, 9% formaldehyde, 70% picric acid). The cervical spinal cord region was dissected out and post-fixed overnight at 4°C in Bouin's post-fixative solution (9% formaldehyde, 70% picric acid). The following day the tissue was cryoprotected by immersion in 10% sucrose for 2 hours, 20% sucrose for 2 hours, and 30% sucrose overnight. The tissue was frozen in powdered dry ice, mounted in Tissue-Tek (Miles 4583) at -18°C, and 30 µm serial sagittal sections were mounted onto gel-subbed glass slides. Each slide also contained one or more 30 µm coronal sections through the lateral ventricles from the brain of the same animal to serve as a positive control. Slides were kept at

-80°C until processed. **Immunohistochemistry:** Slides were rinsed in PBS 3 x 15 minutes in 0.1M PBS at room temperature, hydrolyzed with 1N HCl for 60 minutes at 37°C, rinsed for 3 x 15 minutes in 0.1M PBS at room temperature, placed in 6% H₂O₂ in methanol for 30 minutes at room temperature, rinsed for 3 x 15 minutes in 0.1M PBS at room temperature, and incubated in 10% normal horse serum (Sigma H-0146) in 0.1M PBS for 20 minutes at room temperature. Slides were incubated overnight at room temperature in anti-BrdU monoclonal antibody (Becton 7580) that was diluted 1:50 in 0.1M PBS containing 1.5% normal horse serum and 0.3% Triton. The following day the slides were rinsed in PBS for 3 x 10 minutes in 0.1M PBS at room temperature, incubated with biotinylated horse anti-mouse IgG (Vector BA-2000) for 2 hours at room temperature, rinsed for 3 x 15 minutes in 0.1M PBS at room temperature, incubated in ABC reagent (Vector PK-6100) for 2 hours at room temperature, rinsed for 3 x 15 minutes in 0.1M PBS at room temperature, and developed with DAB reagent for 2 to 4 minutes. The slides were coverslipped with Aqua Polymount (Polysciences 18606). The number of BrdU positive cells was counted per cervical spinal cord section. Some BrdU labelled cells were found in the saline control sections. Treatment with either EGF or bFGF resulted in a significant increase in the number of BrdU labelled cells seen compared to control. The combination of EGF plus bFGF produced even a greater amount of BrdU positive cells per section.

Example 15.

EGF and FGF is infused into the lateral ventricles (see Example 1) (or other CNS ventricular regions that contain quiescent stem cells). The CNS stem cells are then isolated and proliferated *in vitro* using proliferation methods such as that described in Example 2. This procedure results in an increase in the number of stem cells that are generated and an increase in the number of neurospheres (see Fig. 5). Neurospheres generated by this method are used as a source of donor cells for later transplantation into degenerated areas of human adult CNS. Neurospheres can also be proliferated accordingly from a patient's own CNS stem cells and transplanted back into the patient.

All references cited herein are hereby incorporated by reference.

WHAT IS CLAIMED IS:

1. A method for the *in situ* proliferation, and optionally the differentiation, of a CNS precursor cell located in the tissue lining a CNS ventricle of a mammal, said method comprising administering at least one growth factor to said CNS ventricle to induce the proliferation and/or differentiation of said cell.
2. The method of Claim 1 wherein said at least one growth factor is epidermal growth factor.
3. The method of Claim 2 further comprising administering fibroblast growth factor to said ventricle.
4. The method of any of Claims 1 to 3 wherein said growth factor is delivered to said ventricle by an osmotic pump.
5. The method of any of Claims 1 to 4 wherein said CNS ventricle is the lateral ventricle of the forebrain.
6. The method of any of Claims 1 to 4 wherein said CNS ventricle is the central canal.
7. The method of any of Claims 1 to 6 further comprising administering Bcl-2 to said ventricle.
8. A method for the *in situ* genetic modification of a CNS precursor cell located in tissue lining a CNS ventricle of a mammal, said method comprising administering genetic material to said CNS ventricle to infect said cells, said genetic material being capable of encoding at least one neurological agent.
9. The method of Claim 8 wherein said CNS ventricle is the lateral ventricle of the forebrain.
10. The method of Claim 8 wherein said CNS ventricle is the central canal.

11. The method of any of Claims 8 to 10 wherein said genetic material is contained within a retroviral construct.
12. The method of any of Claims 8 to 11 further comprising administering at least one growth factor to said ventricle to induce the proliferation and/or
5 differentiation of said cell.
13. The method of Claim 12 wherein said growth factor is epidermal growth factor.
14. The method of Claim 13 further comprising administering fibroblast growth factor to said ventricle.
- 10 15. The method of any of Claims 8 to 14 wherein said neurological agent is selected from the group consisting of growth factors, growth factor receptors, neurotransmitters, neurotransmitter receptors, neuropeptides, growth factor synthesizing enzymes, and neurotransmitter synthesizing enzymes.
- 15 16. The method of *in vitro* proliferation of precursor cells comprising the steps of:
- (a) administering at least a first growth factor to a CNS ventricle of a living mammal, said CNS ventricle being lined by tissue comprising at least one precursor cell;
 - (b) removing said tissue from said mammal;
 - 20 (c) dissociating said neural tissue to separate said precursor cell from tissue, and
 - (d) culturing said precursor cell in a culture medium comprising at least a second growth factor that is the same as or different from said first growth factor and proliferating said cell.
- 25 17. The method of Claim 16 wherein said first growth factor is epidermal growth factor.

18. The method of Claim 17 wherein step (a) further comprises administering fibroblast growth factor to said ventricle.
19. The method of any of Claims 16 to 18 wherein said second growth factor is epidermal growth factor.
- 5 20. The method of Claim 19 wherein said culture medium of step (d) further comprises fibroblast growth factor.
21. The method of any of Claims 16 to 20 wherein said ventricle is a lateral ventricle of the forebrain of said mammal.
22. The method of any of Claims 16 to 20 wherein said ventricle is the central
10 canal.
23. A method of treating a neurological disorder of a mammal comprising administering a composition comprising at least a first growth factor to a ventricle of the central nervous system of said mammal, said ventricle being lined by tissue comprising at least one precursor cell, said growth factor inducing the *in situ*
15 proliferation and, optionally, differentiation of said precursor cell to form tissue comprising proliferated precursor cells.
24. The method of Claim 23 wherein said composition is administered to said ventricle by an osmotic pump.
25. The method of Claim 23 or 24 wherein said neurological disorder affects the
20 brain and said ventricle is located within said brain.
26. The method of Claim 25 wherein said composition comprises EGF, bFGF and heparan sulphate, and said neurological disorder is Parkinson's disease.
27. The method of Claim 23 wherein said neurological disorder affects the spinal cord and said ventricle is the central canal.

28. The method of Claim 23 wherein said first growth factor is epidermal growth factor.
29. The method of Claim 28 further comprising administering fibroblast growth factor to said ventricle.
- 5 30. The method of Claim 23 further comprising the additional steps of:
removing said tissue comprising proliferated precursor cells, dissociating said tissue
to separate said proliferated precursor cells, culturing said proliferate precursor cells
in a culture medium *in vitro* comprising at least a second growth factor to further
proliferate and, optionally, differentiate said precursor cells, and implanting said
10 proliferated and/or differentiated precursor cells into said ventricle of said mammal.
31. The method of Claim 30 wherein said second growth factor is epidermal growth factor.
32. The method of Claim 31 wherein said culture medium further comprises fibroblast growth factor.
- 15 33. The method of Claim 23 further comprising the additional steps of:
removing said tissue comprising proliferated precursor cells, dissociating said tissue
to separate said proliferated precursor cells, culturing said proliferate precursor cells
in vitro in a culture medium comprising at least a second growth factor that is the
same as or different from said first growth factor to further proliferate said
20 precursor cells, genetically modifying said proliferated precursor cells with genetic
material capable of encoding at least one neurological agent, and implanting said
genetically modified precursor cells into said ventricle of said mammal.
34. The method of Claim 33 wherein said second growth factor is epidermal growth factor.
- 25 35. The method of Claim 33 wherein said culture medium further comprises fibroblast growth factor.

36. A method of treating a neurological disorder of a mammal comprising administering genetic material to a CNS ventricle of a mammal, said ventricle being lined by tissue comprising at least one precursor cell, said precursor cell being genetically modified *in situ* by said genetic material, said genetic material being
5 capable of encoding at least one neurological agent.
37. The method of Claim 36 wherein said genetic material is contained within a retroviral construct.
38. The method of Claim 36 or 37 further comprising administering at least one growth factor to said ventricle to induce the proliferation and/or differentiation of
10 said cell.
39. The method of Claim 38 wherein said growth factor is epidermal growth factor.
40. The method of Claim 39 further comprising administering fibroblast growth factor to said ventricle.
- 15 41. The method of any of Claims 38 to 40 wherein said at least one growth factor is administered to said ventricle by an osmotic pump.
42. The method of any of Claims 36 to 41 wherein said neurological agent is selected from the group consisting of growth factors, growth factor receptors, neurotransmitters, neurotransmitter receptors, neuropeptides, growth factor
20 synthesizing enzymes, and neurotransmitter synthesizing enzymes.
43. The method of any of Claims 36 to 42 wherein said neurological disorder affects the brain and said ventricle is located within said brain.
44. The method of any of Claims 36 to 42 wherein said neurological disorder affects the spinal cord and said ventricle is the central canal.

45. Use of a composition for the preparation of a medicament that induces the *in situ* proliferation and/or of a CNS precursor cell located in the tissue lining a CNS ventricle of a mammal, said composition being adapted for delivery to said ventricle and comprising at least one growth factor that induces the proliferation, and optionally, the differentiation of said CNS precursor cell.
46. Use according to claim 45 wherein said growth factor is selected from the group consisting of EGF, amphiregulin, aFGF, bFGF, and TGF α .
47. Use according to claim 45 wherein said composition comprises a combination of EGF and aFGF or EGF and bFGF.
48. Use according to any of claims 45 to 47 wherein said composition further comprises a growth factor that regulates proliferation of precursor cells.
49. Use according to claim 48 wherein said growth factor that regulates proliferation is selected from the group consisting of heparan sulphate, TGF β , activin, BMP-2, CNTF, retinoic acid, TNF α , MIP-1 α , MIP-1 β , MIP-2, NGF, PDGF, interleukins, and the Bcl-2 gene product.
50. Use according to claim 45 wherein said composition comprises EGF, bFGF and heparan sulfate.
51. Use according to 50 wherein said medicament is for the treatment of Parkinson's disease.
52. Use according to any of claims 45 to 51 wherein said composition is contained within an osmotic pump adapted for delivering said composition to said ventricle.
53. Use of a composition for the preparation of a medicament used for the *in situ* genetic modification of a CNS precursor cell located in the tissue lining a CNS ventricle of a mammal, said composition being adapted for delivery to said

ventricle and comprising genetic material capable of encoding at least one neurological agent.

54. Use according to claim 53 wherein said genetic material is contained within a retroviral construct.
- 5 55. Use according to claim 53 or 54 wherein said composition further comprises at least one growth factor that induces the proliferation and/or differentiation of said CNS precursor cell.
56. Use according to claim 55 wherein said growth factor is selected from the group consisting of EGF, amphiregulin, aFGF, bFGF, and TGF α .
- 10 57. Use according to any of claims 53 to 56 wherein said composition further comprises a growth factor that regulates proliferation of precursor cells.
58. Use according to claim 57 wherein said growth factor that regulates proliferation of precursor cells is selected from the group consisting of heparan sulphate, TGF β , activin, BMP-2, CNTF, retinoic acid, TNF α , MIP-1 α , MIP-1 β ,
15 MIP-2, NGF, PDGF, interleukins, and the Bcl-2 gene product.
59. Use according to any of claims 53 to 59 wherein said neurological agent is selected from the group consisting of growth factors, growth factor receptors, neurotransmitters, neurotransmitter receptors, neuropeptides, growth factor synthesizing enzymes, and neurotransmitter synthesizing enzymes.
